# Modelling Competition for Nutrients between Microbial Populations Growing on Solid Agar Surfaces

Author: Daniel Boocock; Supervisor: Dr Conor Lawless

August 14, 2016

---

## ABSTRACT

**Motivation:** Growth rate is a major component of the evolutionary fitness of microbial organisms. When nutrients are plentiful, fast-growing strains come to dominate populations whereas slower-growing strains are wiped out. This makes growth rate an excellent (a useful) surrogate for the health of cells. Measuring the health of cells grown in different genetic backgrounds or environments can inform about genetic interaction and drug sensitivity. In high-throughput procedures such as QFA and SGA, arrays of microbial cultures are grown on solid agar plates and quantitative fitness estimates are determined from growth measurements. Diffusion of nutrients along gradients in nutrient density arising between fast- and slow-growing neighbours is likely to affect growth rate and fitness estimates. However, current analyses assume that cultures grow independently. We study data from QFA experiments growing *Saccharomyces cerevisiae* to test a mass action kinetic model of nutrient dependent growth and diffusion. We try to correct for competition to provide more accurate and precise fitness estimates.

**Results:** Don't know what to say yet.

**Availability and Implementation:** CANS, a Python package developed for the analysis in this paper, is freely available from [github](https://github.com/danielboocock/CANS).

## 1 INTRODUCTION

The bacteria *Escherichia Coli* and yeast *Saccharomyces cerevisiae* are unicellular organisms studied as a model prokaryote and eukaryote respectively. They grow in colonies, where cells may (be clones originating from a single cell or) belong to different genetic strains originating from different individual cells. In favourable conditions, growth is exponential and this makes growth rate a major component of fitness; faster growing strains quickly come to dominate the population. At a certain point growth becomes limited and a stationary phase is reached. For unicellular organisms, growth rate is equal to cell cycle progression rate. Evolutionary pres-

sure has led to rapidly dividing organisms (such as *E. Coli* and *S. cerevisiae*) with compact genomes of essential genes. These genes have been conserved in other species over billions of years of evolution. The eukaryote *S. cerevisiae*, is particularly useful for the study of other eukaryotes such as humans.

The growth rate of microbial organisms is measurable and is often used to determine fitness. In experiments, cell cultures are commonly grown in two types of medium. In spot tests (phenotypic array), cultures are pinned or inoculated on the surface of a solid agar containing nutrients. In liquid culture assays, cultures are mixed in a liquid medium containing nutrients. In both cases cultures are incubated and growth is observed. Identical strains can grow differently between the two mediums and disagreement in fitness estimates is currently an issue Baryshnikova *et al.* (2010a) (I couldn't find a paper specifically talking about this issue but they have a correlation plot Fig2a where correlations are worse with a liquid culture study by Jasnos and Korona; in fact the Baryshnikova paper Fig3c seems to say that they had strong correlation in their "high-resolution liquid growth profiling study"). I do not focus on this issue and exclusively study fitness screens using solid agar.

Fitness estimates can be used to infer genetic interaction or drug response and high-throughput methods allow this to be conducted on a genome-wide scale (see e.g. Costanzo *et al.* (2010); Andrew *et al.* (2013)). In a typical genetic interaction screen, a strain is made with a mutation in a query gene. Double mutants are created by introducing a second deletion in this strain. By comparing the growth of double mutants with a control containing a neutral deletion, genetic interactions can be inferred. If a strain is fitter than the control then the deletion is said to suppress the defect of the query gene. If a strain is less fit than the control then the deletion is said to enhance the defect of the query gene. Either scenario suggests that the two genes interact and have a related function. Due to redundancy, single deletions are often non-lethal. (Remove: Knock downs and conditional mutations can also be used.) This allowed

Costanzo *et al.* (2010) to explore  $\sim 75\%$  of the *S. cerevisiae* genome.

Synthetic Genetic Array (SGA) and Quantitative Fitness Analysis (QFA) are high-throughput methods for obtaining quantitative fitness estimates of microbial cultures grown on solid agar (Baryshnikova *et al.*, 2010b; Banks *et al.*, 2012). Typically one query gene and replicates of deletion are contained in a rectangular array on a solid agar plate. Many plates with different query genes and deletions can be grown in high-throughput to explore whole genomes. I study data from QFA which refers to quantitative estimation of fitness by measurement and fitting of growth curves.

In a typical QFA procedure liquid cultures are inoculated onto solid agar (containing nutrients (already mentioned above)) often with 384 cultures in 16x24 rectangular array. Initial inoculum density can be varied to capture more or less of the growth curve. Dilute cultures are inoculated with  $\sim 100$  starting cells (Addinall *et al.*, 2011). Plates are grown in incubation. Photographs of whole plates are taken at timepoints throughout growth which typically covers several days and captures the exponential and stationary growth phases. Photographs are processed by Colonyzer (Lawless *et al.*, 2010) to produce cell density estimates from the optical density of cultures. Past analysis independently fit the logistic model, which describes self-limiting growth, to the timecourse of each culture and quantitative fitness estimates are defined in terms of the growth constant,  $r$ , and carrying capacity,  $K$ . In contrast, SGA typically uses an array of 1536 pinned cultures and an endpoint assay of culture area (a single measurement) to quantify growth. The differential form and solution of the logistic model (Verhulst, 1845) (probably don't need this reference) are given in Equations 1, where  $C$  represents cell density and  $C_0$  is cell density at time zero.

$$\dot{C} = rC \left(1 - \frac{C}{K}\right) \quad (1a)$$

$$C(t) = \frac{KC_0 e^{rt}}{K + C_0(e^{rt} - 1)} \quad (1b)$$

Fitting the logistic model to QFA data requires plate level or culture level parameters for  $C_0$  and culture level parameters for  $r$  and  $K$  making 769 or 1152 parameters per plate of 384 cultures.

//Could remove and just discuss MDR when I get to the results// The growth constant  $r$  could be used as a fitness measure. However, Addinall *et al.* (2011) define a more complicated fitness measure as the product of Maximum Doubling Rate (MDR) and Maximum Doubling Potential (MDP) which they derive from logistic

model parameters. MDR measures the doubling rate at the beginning of the exponential growth phase, when growth is fastest, and MDP is the number of divisions which a culture undergoes from inoculation to the stationary phase.

$$MDR = \frac{r}{\log\left(\frac{2(K-C_0)}{K-2C_0}\right)} \quad (2a)$$

$$MDP = \frac{\log\left(\frac{K}{C_0}\right)}{\log(2)} \quad (2b)$$

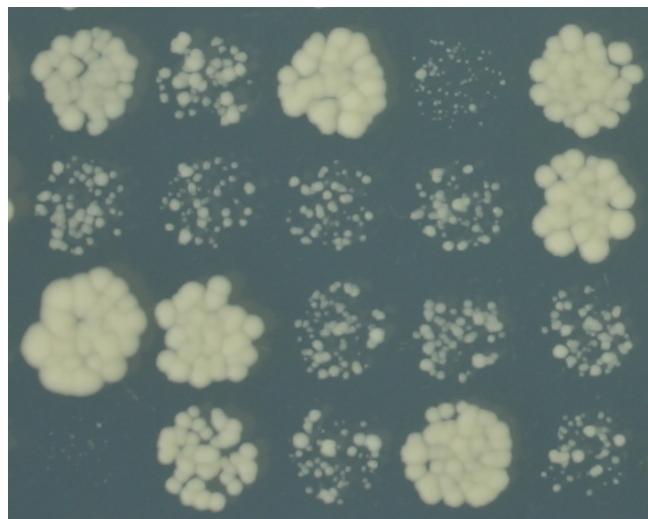

To improve the quality of fits QFA now uses the generalised logistic model which requires an extra parameter for each culture. Standard and generalised logistic model  $r$  are not equivalent so comparison relies on MDR and MDP as fitness measures. The analysis of QFA data using both models is available through the QFA R package (Lawless *et al.*, 2016). //Could remove and just discuss MDR when I get to the results//

//Could remove// Addinall *et al.* (2011) used QFA and *S. cerevisiae* to screen for genes involved in telomere stability which is related to ageing and cancer and has implications for human health and disease. Hits from this study have been successfully followed to discover new biology (Holstein *et al.*, 2014). (To be honest I have no idea what they found in that paper. Maybe I should leave this to biologist and out of my report? We had a more general focus. Obviously I will mention the Addinall paper when I describe p15 in the methods.) //Could remove//

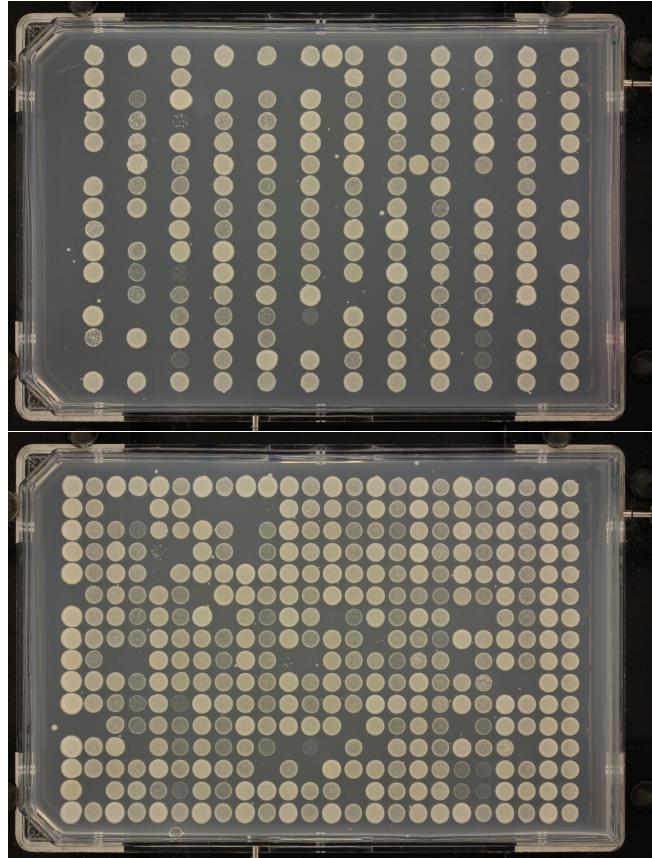

The solution to the logistic model is a sigmoidal curve. Growth begins exponentially with rate  $rC$  and curtails as the population size increases and cells begin to compete for space and nutrients or interact in some other way. Cell density reaches a final carrying capacity  $K$  at the stationary phase. In QFA, nutrients must diffuse through agar to reach cells growing on the surface. It is plausible that the carrying capacity  $K$  represents the point at which nutrients either run out or growth becomes limited by the diffusion of nutrients and is approximately stationary.

Since QFA aims to determine differences in the fitness of microbial strains from measurements of differences in growth, fast and slow growing cultures are often grown side-by-side. Figure 1 shows a section of a QFA plate from a study by Addinall *et al.* where this is the case. (Cultures were inoculated with approximately equal cell density but have grown at different rates to visibly different sizes after  $\sim 2.5$  days.) It is likely that nutrients diffuse along gradients between fast and slow growing neighbours causing growth to appear faster or

slower than would occur if it were independent. Further support for such an effect comes from the experiment shown in Figure 2 where the same cultures are grown in alternate columns on two separate plates but with cultures added or removed from the neighbouring columns in between. Cultures in Figure 2a), where neighbours were removed, grew faster and larger than the same cultures in Figure 2b), where neighbours were added. Despite this, current QFA analysis using the logistic model assumes that cultures grow independently and ignores possible competition effects between neighbours. The sigmoidal curve of the logistic model poorly fits QFA data in many cases. I aim to fit a network model of nutrient dependent growth and diffusion to QFA data to try to correct for competition and increase the accuracy and precision of fitness estimates.

**Figure 1:** 4x5 section of a QFA plate. Taken from a 16x24 format solid agar plate inoculated with dilute *S. cerevisiae* cultures. Image captured at  $\sim 2.5$ d after inoculation and incubation at  $27^\circ\text{C}$ .

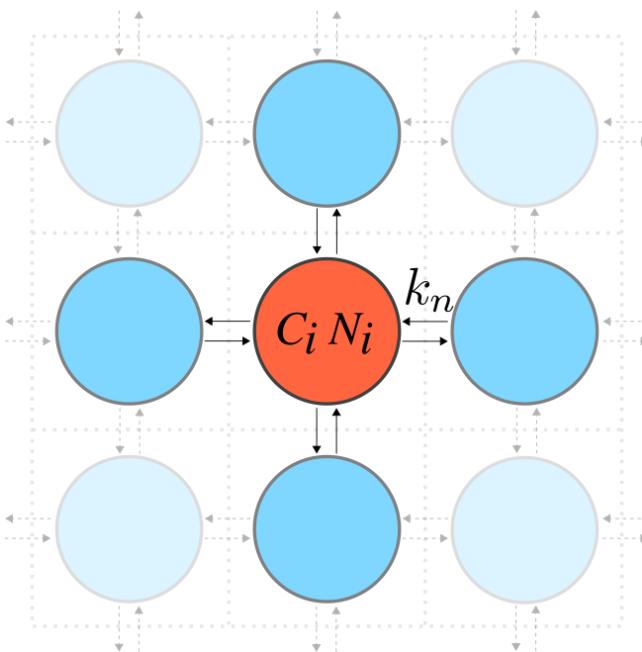

**Figure 2:** An experiment designed to examine competition. A) QFA plate inoculated with a more concentrated *S. cerevisiae* inoculum (no cells inoculated on alternative columns). B) Same as in A, but with strains of similar growth rate inoculated in the positions missing in A.

Alternatively, competition effects could be dealt with experimentally by randomising the location of cultures on repeated plates. This does not require explicit knowledge or modelling of the source of competition but reduces throughput, so, if possible, a modelling approach is desirable. Poisoning of cultures by a signal molecule such as ethanol, which *S. cerevisiae* produces in the metabolism of sugars by fermentation, is another possible source of competition. QFA does not measure nutrients or signal, so if more than one source of competition exists, it will become very difficult to fit a model and randomisation may be the best approach. In an SGA study, Baryshnikova *et al.* (2010a) use statistical techniques to correct for competition between fast and slow growing neighbours in end-point assays of culture area. We hope that modelling the diffusion of nutrients explicitly and using a full network diffusion model will allow us to better correct for competition using fewer repeats. With QFA, we can also use more information by fitting whole growth curves rather than a single endpoint assay so a modelling approach offers to be more powerful. Furthermore, modelling may help us to identify and un-

derstand the source of competition. Simulation of an accurate model will allow us to compare experimental designs and explore ways to reduce competition effects.

//Diffusion Equation: I am probably going to have to reexplain this when I get to the discussion so I could just leave until then// (Reo and Korolev, 2014) use a diffusion equation model to simulate nutrient dependent growth of a single bacterial culture on a petri dish in two-dimensions. It would be too computationally intensive to fit a similar model to a full QFA plate in three-dimensions, especially if we are to use the model to process many plates from high-throughput experiments. Therefore a simpler model of nutrient diffusion is required. //Diffusion Equation//

**Figure 3: Schematic of the competition model.** Each circle represents a culture, indexed  $i$ , growing in a rectangular array on the surface of a nutrient containing solid agar. Arrows represent a network of nutrient diffusion along gradients between cultures.  $C_i$  - amount of cells;  $N_i$  - amount of nutrients;  $k_n$  - plate level diffusion constant; darker blue circles  $\delta_i$  - closest neighbours of culture  $i$ .

Lawless proposed a model of nutrient dependent growth and competition using mass action kinetics and a network diffusion model, hereinafter referred to as the competition model (3,4). A schematic of the model is drawn in Figure 3. In the competition model, the nutrient dependent division of cells is represented by the reaction equation,

where  $C$  is a cell,  $N$  is the amount of nutrients required for one cell division, and  $b$  is a rate constant for the reaction. Separate reactions (3) with growth constant  $b_i$

are defined for each culture, indexed  $i$ , on a plate. Mass action kinetics is used to derive rate equations for the amount of cells and nutrients associated with each culture,  $C_i$  and  $N_i$ . This gives us the rate equation for  $C_i$  (4a) and the first term in the rate equation for  $N_i$  (4b). The rate of nutrient diffusion between culture  $i$  and its closest neighbours, belonging to the region  $\delta_i$ , is modelled by the second term in (4b), where  $k_n$  is a nutrient diffusion constant which is shared across a plate.

$$\dot{C}_i = b_i N_i C_i, \quad (4a)$$

$$\dot{N}_i = -b_i N_i C_i - k_n \sum_{j \in \delta_i} (N_i - N_j). \quad (4b)$$
